Abstract

A long-standing conceptual model for deep submarine eruptions is that high hydrostatic pressure hinders degassing and acceleration, and suppresses magma fragmentation. The 2012 submarine rhyolite eruption of Havre volcano in the Kermadec arc provided constraints on critical parameters to quantitatively test these concepts. This eruption produced a $> 1 \text{ km}^3$ raft of floating pumice and a 0.1 km^3 field of giant ($>1 \text{ m}$) pumice clasts distributed down-current from the vent. We address the mechanism of creating these clasts using a model for magma ascent in a conduit. We use water ingestion experiments to address why some clasts float and others sink. We show that at the eruption depth of 900 m, the melt retained enough dissolved water, and hence had a low enough viscosity, that strain-rates were too low to cause brittle fragmentation in the conduit, despite mass discharge rates similar to Plinian eruptions on land. There was still, however, enough exsolved vapor at the vent depth to make the magma buoyant relative to seawater. Buoyant magma was thus extruded into the ocean where it rose, quenched, and fragmented to produce clasts up to several meters in diameter. We show that these large clasts would have floated to the sea surface within minutes, where air could enter pore space, and the fate of clasts is then controlled by the ability to trap gas within their pore space. We show that clasts from the raft retain enough gas to remain afloat whereas fragments from giant pumice collected from the seafloor ingest more water and sink. The pumice raft and the giant pumice seafloor deposit were thus produced during a clast-generating effusive submarine eruption, where fragmentation occurred above the vent, and the subsequent fate of clasts was controlled by their ability to ingest water.

Keywords: submarine eruption; pumice; fragmentation; raft; conduit flow; X-ray tomography

Highlights:

Havre magma entered the ocean before fragmenting.

Clasts were produced by quenching buoyant magma in the ocean.

Buoyant > 1 m diameter pumice blocks floated to the ocean surface.

Clasts with enough isolated porosity and trapped gas floated in a raft while the rest sank.

1. Introduction

Submarine volcanic eruptions may be fundamentally different from those on land owing to the high hydrostatic pressure provided by the ocean which inhibits degassing and hence magma acceleration and fragmentation. Our understanding and record of such eruptions are limited by the challenge in directly witnessing eruption processes and sampling and characterizing the deposits from those eruptions. Indeed, overcoming this biased understanding of volcanic eruptions was highlighted by the 2017 National Academies report (National Academies, 2017): “What processes govern the occurrence and dynamics of submarine explosive eruptions”?

Silicic magmas that erupt more than a few hundred meters below sea-level give rise to eruption styles distinct from those on land owing to the contrasting properties of the ambient fluid (water vs air) into which the magmas erupt (Cashman and Fiske, 1991). For example, clasts that erupt at the seafloor are initially buoyant, but ingest water into pore space as they cool (e.g.,

Whitham and Sparks, 1986); hence fragmented magma can either rise to the surface to form rafts, or feed submarine density currents if the clasts become waterlogged (Allen and McPhie, 2009).

One distinctive facies of both modern and ancient clastic deposits from submarine silicic eruptions is voluminous deposits of giant (>1 m) pumice clasts (e.g., Kato, 1987; Kano et al., 1996; Kano, 2003; Allen and McPhie, 2009; Allen et al., 2010; Jutzeler et al., 2014). These clasts often have one or more quenched margins with curvilinear joints perpendicular to the cooling surface that suggest they quenched in water (e.g., Wilson and Walker, 1985; Allen et al., 2010; Von Lichten et al., 2016; Figure 1). Otherwise, submarine pumice vesicularities are similar to those produced in subaerial Plinian eruptions (e.g., Barker et al., 2012) and hence it has been proposed that fragmentation mechanisms are also similar for large (> 1 km³) submarine equivalents (e.g., Allen and McPhie, 2009; Shea et al., 2013). There are, however, textural differences: pumice clasts from deep submarine eruptions tend to have smaller bubble number densities, lack very small vesicles (<10 µm), and display a narrower range of modal vesicle sizes (Rotella et al., 2015). Clasts have also been proposed to form from buoyant bubbly magma as it exits the vent by “viscous detachment or by the development of cooling joints” (Rotella et al., 2013), an eruption style that would not fit neatly into either the “effusive” or “explosive” categories used to describe subaerial eruptions. Pumice clasts can also form by spallation from a pumiceous carapace on effusive domes (e.g., Cas and Wright, 1987; Kano, 2003; Allen et al., 2010).

In July 2012, approximately 1.2 km³ of rhyolite pumice clasts erupted at a water depth of 900 m from the submarine Havre volcano in the Kermadec volcanic arc (Carey et al., 2014; Figure 1). The majority of the pumiceous material formed a raft of floating clasts that was widely dispersed in the western Pacific Ocean (Jutzeler et al., 2014; Carey et al., 2018). A second clastic product of this eruption is a 0.1 km³ deposit of giant pumice clasts on the seafloor around the inferred vent. An outstanding question is whether these seafloor giant pumice clasts and raft pumice originated from the same eruptive phase. Though not conclusive, the vesicularities, composition, microtextures (e.g., bubble number densities, crystallinity, microlite mineralogy), and macrotextures (e.g., banding), are similar as is their primary axis of dispersal (Carey et al., 2018). If the raft and seafloor pumice did originate from the same eruptive episode, their different fate, i.e., whether they floated or sank, thus requires seafloor giant pumice to ingest water more effectively than clasts that were transported into the raft.

Here we use a model for magma ascent, constrained by estimates of the eruption rate for the pumice raft and a variety of measurements on erupted materials, to show that buoyant magma reached the seafloor prior to fragmenting. We then investigate how pumice clasts from the raft and seafloor ingest water as they cool and find that seafloor pumice ingest water more efficiently by trapping very little gas. We thus infer that vesicular coherent magma extruded into the ocean. The magma quenched and fragmented non-explosively to form the pumice clasts that then either remained afloat because they retained enough gas or, if they waterlogged, settled to the seafloor.

2. Methods

2.1 Conduit model

Magma ascent is simulated using a one-dimensional two-phase model for steady flow, modified from Degruyter et al. (2012) and Kozono and Koyaguchi (2009). Pressure at the vent is 9 MPa corresponding to a water depth of 900 m. The conduit length is 8.1 km with a pressure at its base of 200 MPa. Crystallinity is 5% (Carey et al., 2018) and crystals do not grow or nucleate during ascent. The effects of crystals and bubbles on viscosity are based on the models of Costa (2005) and Llewellyn and Manga (2005), respectively (supplement S1). Water content in the melt is 5.8 weight % based on 16 plagioclase-hosted melt inclusions from a seafloor giant pumice clast (supplement S2). Number density of bubbles is 10^{14} m^{-3} (Rotella et al., 2015), high enough that we can assume equilibrium bubble growth (Gonnermann and Manga, 2005); we obtain similar ascent rates for number densities 100 times lower and higher. The effects of temperature and dissolved water on viscosity are computed using Giordano et al. (2008) and the measured composition (supplement S3) and water content. Temperature is set to $850 \pm 20 \text{ }^{\circ}\text{C}$ based on cpx-opx Fe-Mg exchange (Putirka, 2008) in ten measured cpx and opx compositions. Magma can fragment in the conduit if the strain-rate $\dot{\gamma}$ exceeds a critical value (e.g., Papale, 1999)

$$\dot{\gamma} > 10^{-2} G / \mu, \quad (1)$$

where $G = 10^{10} \text{ Pa}$ is the shear modulus (e.g., Simmons, 1998) and μ is the melt viscosity. We compute both the strain-rate at the conduit walls and the elongation strain-rate in the center of the conduit.

It is important to recognize that in addition to uncertainties in magma properties there are also model assumptions that affect strain-rates, ascent velocity, and vesicularity at the vent. For

example, the ascending magma is assumed to be isothermal and Newtonian, we neglect viscous heating and shear localization in the magma, and we do not permit non-equilibrium bubble growth. We also use a geometrically idealized conduit shape. In addition, we assume that at any given depth the bubble size is uniform and use this bubble size to compute a permeability. There are, however, bubbles much larger than the mean size which, owing to the nonlinearity of permeability-bubble size relationships, could lead to higher permeability and more outgassing.

2.2 Floatation experiments

To determine the propensity for Havre pumice clasts to remain afloat after reaching the raft at the ocean surface, we conducted 11 experiments in which we measured the amount of liquid water and trapped gas within cm-sized clasts from the Havre raft (7 samples) and fragments of seafloor giant pumice (4 samples). We heated dry raft clasts and giant pumice fragments to a range of temperatures up to 700°C and placed them on the water surface for ten minutes. We then rapidly encased the clasts in wax – to minimize further changes in the distribution of internal fluids – and imaged the clasts at 1.22 μm resolution using X-ray computed microtomography (XRT) with 30 keV monochromatic X-rays. To enhance the absorption contrast between the water and glass, we used a 13 weight% potassium iodide solution. Additional imaging details are provided in supplement S4. From the XRT images, we identified the volumetric content of glass, liquid water, and trapped gas within the clasts using machine learning algorithms to segment these three phases (Fauria et al., 2017).

To further quantify pumice floatation dynamics, we measured the floatation time of room temperature raft and seafloor clasts. To measure floatation times, we placed dry and ambient temperature clasts in water and noted the time at which they sank. Before the experiments, we cleaned the clasts in an ultrasonicator for ~10 min and then dried them. Once the experiments were initiated, we monitored the clasts with a camera and noted the time at which the clasts sank to the nearest minute. If clasts continued to float after the first six months of the experiments, we stopped monitoring with a camera and began checking on the clasts approximately daily and then weekly once the experiments progressed past the first year.

We measured clast weight before and after the experiments. For a subset of the clasts, primarily the seafloor clasts, we measured clast volume using photogrammetry. Specifically, we took 100-180 photographs per clast using a Canon DSLR camera with an extension tube. We processed the images and constructed volume models (Poisson surface reconstructions) using VisualSFM and MeshLab softwares. In cases where the clasts were too small to accurately measure volume using photogrammetry, we estimate pumice volume using pumice mass assuming a clast porosity of 83% (Carey et al., 2018).

2.3 Isolated porosity

Differences in isolated porosity between the raft and seafloor samples are unresolvable in the XRT scans. We thus use helium pycnometry to quantify the connected and unconnected pore space. Samples were cored, washed, dried, and weighed. The volume of the cylindrical cores was calculated based on the mean of 10 measurements of the sample diameter and height. The

volume of the solid phase and isolated porosity was measured using a He-pycnometer at the University of Oregon using methods described in Giachetti et al. (2010). The pycnometry measurements and bulk volume were used to calculate the connected porosity. One seafloor sample and one raft sample were crushed, weighed, and analyzed using He-pycnometry in order to determine the solid density. The bulk vesicularity was calculated from the solid density, bulk volume, and bulk density. The isolated vesicularity was calculated from the difference between the bulk vesicularity and connected vesicularity.

3. Results

Figure 2 shows how ascent velocity, mean bubble size, melt viscosity, and vesicularity vary with depth in the conduit for conduit radii of 3, 21 and 33 m. The corresponding mass eruption rates are 4.2×10^3 , 1.0×10^7 and 6.2×10^7 kg/s respectively. This model reproduces the observed vesicularity of about 80-90 % and modal vesicle size (Rotella et al., 2015; Carey et al., 2018). A conduit radius of 21 m leads to a mass eruption rate similar to the time-averaged value inferred from the volume of the pumice raft and the estimated duration of the raft-forming stage of the eruption, 9×10^6 kg/s (Carey et al., 2018). For this eruption rate, Figure 2b shows that the gas and melt remain coupled and there is negligible outgassing during ascent. The model does not account for any further modification of vesicularity of clasts after they enter the ocean.

There are uncertainties in all model parameters including, critically, those that affect viscosity: water content and temperature. However, the main conclusions are not sensitive to reasonable ranges in these parameters. For example, if we reduce the water content to 5% and

temperature to 820 °C, even for an eruption rate an order of magnitude greater than inferred, 1×10^8 kg/s, the strain-rate is still a factor of 5 too low to cause melt to fragment based on equation (1).

Figure 3 shows that reheated ($> 500^\circ\text{C}$) Havre raft pumice can retain enough gas to remain buoyant. By comparison, fragments from the seafloor giant pumice are almost fully saturated (< 0.05 volume fraction gas) after they are reheated above 500°C and placed on the water surface. The results from these experiments demonstrate that hot Havre seafloor giant pumice draw in considerably more water than raft pumice. In raft pumice, some of the gas is trapped by the infiltrating water (red arrow), but there is also a significant amount of unconnected porosity (isolated bubbles). This difference is further highlighted by the pycnometry measurements. Figure 4 shows the connected and unconnected porosity analysis and reveals that seafloor giant pumice has fully connected porosity whereas raft pumice always contains isolated bubbles. These differences may be documenting samples from different parts of the conduit, or samples that experienced different vesiculation histories in the water column. A thorough analysis of textures from raft and seafloor samples may reveal not only why some clasts float, but provide further insights into ascent processes in the conduit and water column.

Figure 5 shows clast volume versus floatation time. We identify clasts that were still floating at the time of manuscript submission with red outlines. We find that floatation time increases with clast size and that raft pumice float orders of magnitude longer than seafloor pumice. We compare pumice floatation times to a diffusion model for pumice floatation from Fauria et al. (2017). The model predicts that floatation time scales as

229

$$\tau = \frac{4R^2}{D_a\theta^2}, \quad (2)$$

230 where τ is time, $2R$ is clast diameter, $D_a = 1.9 \times 10^{-9} \text{ m}^2/\text{s}$ is air-water diffusivity (Fauria et al.,
231 2017), and θ is the fraction of pore space containing liquid water. The shaded region in Figure 5
232 shows predictions of equation (2) with θ between 0.1 and 0.5. Seafloor clasts match the diffusion
233 model prediction while raft pumice float much longer than predicted and, indeed, have yet to
234 sink. The presence of isolated bubbles (Figure 4) may explain why cold raft pumice float much
235 longer than theoretical models predict.

236

237

238 **4. Discussion**

239

240 We now address in order three basic questions about the 2012 Havre eruption. Where and why
241 did the magma fragment? What processes form meter-sized clasts? Why do some pumice clasts
242 float (raft pumice) and others sink (seafloor giant pumice)?

243

244 *4.1 Fragmentation*

245

246 From the conduit model, strain rates never become large enough to cause brittle fragmentation
247 within the conduit of the Havre eruption. Instead, at 86% vesicularity, the erupting magma is less
248 dense than sea water and hence will continue to rise above the vent rather than creating a dome.

249 What processes then create the pumice? We do not favor buoyant detachment of blebs by
250 gravitational instabilities, one mechanism suggested for example by Rotella et al. (2013),

because the separation of blebs is slow compared to the inferred extrusion velocity for the Havre eruption and we did not see fluidal-shaped clasts either near the vent or in samples from the raft. For a bleb of length l and radius r buoyantly rising above the extruding magma, the velocity $dl/dt \approx \frac{(\rho_w - \rho_c)gr^2}{\mu} \ln(l/r)$, where ρ_c is clast density, ρ_w is water density, and g is gravity (Olson and Singer, 1985). This is a Stokes flow scaling, appropriate because the magma viscosity controls extrusion prior to fragmentation. Choosing $l = 2r$ for equant bleb, $\mu = 5 \times 10^6$ Pa s (Figure 2), $\rho_w - \rho_c = 500 \text{ kg m}^{-3}$ (Rotella et al., 2015; Carey et al., 2018), and $l=5$ m, we obtain an ascent speed of 4 cm/s, much less than the velocity at the vent of 14 m/s (figure 2). The melt is so viscous that ductile processes are too slow to produce clasts. Instead, we suggest that the surface of extruded magma will quench in the ocean, producing a network of cracks perpendicular to the magma surface. Highly vesicular magma is prone to quench fragmentation and the temperature difference between magma and seawater is sufficient to create cracks (van Otterloo et al., 2015), possibly aided by continued vesiculation. Crack propagation speeds can be tens to hundreds of meters per second (van Oterloo et al., 2015) so that a large volume of fragmented debris can be produced very quickly. Although a range of fragment sizes will be produced, they will not be able to separate and rise unless they can also float upwards fast enough from the extruding magma. Smaller fragments may weld together, or may break off larger clasts or the side of the extruding spine of magma if the spine extends above the vent.

4.2 Separating pumice from extruding magma

The terminal rise speed U of clasts produced by quenching and surrounded by water, idealized here as spherical with radius R , is

$$U = \sqrt{\frac{8(\rho_w - \rho_c)gR}{3\rho_w C_D}} \quad (3)$$

Given the very high Reynolds number ($\sim 10^7$), the drag coefficient C_D is approximately 0.3 (e.g., Batchelor, 1967). Equation (2) also neglects entrainment by the buoyant warm water heated by the clasts, which would increase velocity. With a conduit radius of 21 m the vent velocity is 14 m/s (Figure 2), and clasts with $R > 4.5$ m will rise faster than the extrusion speed, at least before they ingest water. Exit velocity is inversely related to conduit radius owing to mass conservation. If the vent widens by 40% at the seafloor, the minimum radius R for detachment decreases to 1.2 m. There are uncertainties in both the mass eruption rate that constrains the exit velocity and the parameters that affect the minimum size of clasts computed from equation (3), but predicted meter-sized clasts are similar to typical sizes of the giant pumice on the seafloor, averaging 1-1.6 m near the vent and increasing with dispersal distance (Carey et al., 2018).

4.3 Reaching the sea surface

Clasts that detach from the extruded magma will rise through the ocean until they saturate with water. Once saturated, clasts will become negatively buoyant and sink to the seafloor. For meter-sized clasts, water ingestion is limited not by permeability but by the ability of water vapor in the clast to cool, condense and draw in liquid (appendix A). As cooling is slower than permeable flow, the rate of heat loss from the interior of the pumice will determine the time to saturation. To compute the evolution of clast density through water ingestion, and hence their ascent through the ocean, we model the cooling, condensation, and thus flow of liquid water into

spherically symmetric clasts using experimentally measured rates of heat loss, and compute the rise speed of the clasts using equation (3) from the time-evolving mean clast density (assuming fully connected porosity). We allow gas in the clasts to expand as the ambient pressure decreases (appendix B) which is significant because water vapor density is $> 15 \text{ kg/m}^3$ at 900 m water depth and $\sim 1 \text{ kg/m}^3$ at the surface. Additional joints within clasts would enhance water ingestion and cooling beyond what we model. We neglect any possible further vesiculation within clasts as they rise through the ocean. Although clasts may remain hot as they ascend and can continue to exsolve water, vesicles need not grow if the pore space is connected to permit gas leakage to the ocean (e.g., Kueppers et al., 2012). Figure 6 shows the time required for clasts of different vesicularities to reach the ocean surface before they become negatively buoyant in water. Meter-sized clasts, such as the seafloor giant pumice, are expected to reach the raft at the ocean surface and will have ingested little water. The initial sizes of raft pumice are not known, but Figure 6 suggests that a minimum size of about one meter is required for clasts to reach the surface.

4.4 To sink or float?

The long-term fate of floating pumice on the sea surface depends on their ability to ingest additional water as they float. The ascent model predicts that there is virtually no liquid in meter-sized and larger clasts as they reach the sea surface owing to the expansion of vapor in the clasts during ascent (appendix B). However, the seafloor deposit of giant pumice comprises clasts up to 9 m in diameter (Carey et al., 2018). Some of those may include pumices that are large enough to reach the sea surface, but are trapped underneath floating pumice and remain fully surrounded by water, in which case we would expect them to sink once the water vapor cools and condenses

(Allen et al., 2008). Others must have reached the sea surface and subsequently saturated with water.

Once pumice reaches the sea surface, we expect air to replace most of the water vapor in the pore space because gas diffusion and exchange is rapid, and is further enhanced as clasts crack or break. Air-filled pumice is known to float much longer (e.g., Whitham and Sparks, 1986; Manville et al., 1989; Dufek et al., 2007; Jutzeler et al., 2017) than the time it takes for porous flow to allow water to infiltrate (Vella and Huppert, 2007). Instead, the ability of clasts to float is controlled by the propensity of the infiltrating water to trap gas bubbles within the pore space and/or the presence of isolated vesicles. If enough gas is trapped during infiltration of water, the clasts will float until this gas diffuses through the water and out of the clast (Fauria et al., 2017).

The difference in isolated and connected porosity can partially explain the propensity for raft pumice to float, however, additional gas trapping is required for most clasts (Figure 4). Our experiments confirm that fragments of seafloor giant pumice ingest more water and trap less gas than raft pumice, and hence more rapidly become negatively buoyant. The presence of elongate "tube" vesicles in some seafloor pumice has further implications for why some clasts sink preferentially to others. The elongate structure, high connectivity and anisotropic permeability of such vesicles would permit rapid clast saturation and subsequent sinking to the seafloor (Wright et al., 2006). The diversity of these textures within pumice deserves more detailed microtextural analysis.

We thus propose that what separates pumice into the raft is their ability to trap gas and the presence of isolated vesicles; clasts that cannot retain enough gas sink. Those that trap gas and/or have sufficient isolated vesicles float. Presumably the difference in gas trapping results from differences in topology of the pore space such as the number of dead-end pores. We could not, however, identify any key differences in our images. We note several caveats, however. First, we are not able to do experiments on meter-sized raft or seafloor clasts owing to the lack of intact samples and our inability to measure and image the infiltration at such large scales. We thus assume that the smaller fragments we imaged are representative of the larger clasts from their respective units. Second, we do experiments on quenched samples, whereas the vesicularity and texture of the pumice may evolve during quenching and also after their initial fragmentation. Larger clasts should take longer to ingest water, explaining why seafloor pumice clast size increases with distance from the vent (Carey et al., 2018).

4.5 The effusive eruption of Havre

The raft-forming Havre eruption was not explosive in the same manner as subaerial pumice clast-forming eruptions. This submarine style of pumice-generating eruption requires an eruption depth that is not-too-deep and not-too-shallow (Figure 7). In deeper water, with the critical depth depending on the water content of the melt, the magma will not be buoyant and will form a lava flow or dome (Figure 7c). In shallower water, the melt viscosity will be higher owing to greater gas exsolution and the magma may undergo brittle fragmentation in the conduit (Figure 7a). For the Havre mass eruption rate, composition, and water content, a vent depth of 2.8 km will lead to the erupting magma being denser than seawater (1030 kg/m^3), and a vent shallower

than 290 m will allow the magma to fragment in the conduit (21 m radius) assuming that the criterion given by equation (1) is accurate. It is worth noting that the Taupo eruption which also produced giant pumice fragments, and was dominated by Plinian-phreatoplinian explosions and magmatic fragmentation in the conduit, occurred in water depths that were never more than 200 m (Wilson and Walker, 1985; Houghton et al., 2003). Mass discharge rate also matters because low ascent rates enable outgassing. For example, at Havre multiple lava domes with low-to-moderate vesicularity extruded in 2012 at the same water depth as the vent that produced the giant pumice clasts. At Sumisu Dome C in the Sumisu Dome Complex, Izu Bonin Arc, Japan, silicic pumiceous dome carapaces at 1100-1300 mbsl have high vesicularity, between 60 – 85%, and did not produce a clastic deposit (Allen et al., 2010).

The 2012 eruption that produced the pumice raft partly conforms to the eruption style proposed by Rotella et al. (2013) in which bubbly magma enters the ocean and clasts detach from the extruding magma; we favor “cooling joints” and other mechanical stresses over “viscous detachment” for Havre because the effusion velocity is so high and because we lack evidence for any wholly or partly bleb-shaped clasts; ductile processes, however, may be important for creating floating clasts from less viscous magmas (e.g., Kueppers et al., 2012).. As noted by others (e.g., Cas and Giordano, 2014; Allen and McPhie, 2009; White et al. 2015), terminology such as explosive and effusive, developed for subaerial eruptions and their deposits, may not translate well to the submarine realm where high hydrostatic pressure and the cooling effects of liquid water can modulate fragmentation.

Given that submarine giant pumice deposits are common products of historical eruptions and well documented in the rock record (Reynolds et al., 1980; Kano et al., 1996; Risso et al., 2002; McPhie and Allen, 2003; Kano, 2003; Allen and McPhie, 2009; Allen et al., 2010; Jutzeler et al., 2014; Von Lichten et al., 2016), we infer that the 2012 Havre eruption may be an example of a relatively common style of deep submarine volcanic eruption. Modern intra-oceanic arcs, such as the Kermadec, Izu, Bonin, Mariana, and South Sandwich arcs contain many deep submarine silicic volcanoes, and similar eruptions may be common.

5. Conclusions

The 2012 pumice raft-forming eruption was produced from a vent that extruded buoyant vesicular rhyolite into the sea at speeds > 10 m/s. This lava fragmented by quenching in the ocean to produce three subpopulations of clasts. Large clasts (> 1 m) rose to the sea surface without ingesting enough water to sink. Those large clasts with sufficient isolated vesicles and/or trapped gas remained afloat in the raft. Large clasts that did not retain enough gas, and those that were trapped beneath the pumice raft, sank to create the seafloor giant pumice. Smaller clasts would not have reached the surface, ingesting water quickly and settling close to the vent, or were transported by currents if small enough.

The eruption style documented at Havre may be dominant for submarine silicic eruptions, as most submarine vents are at depths greater than a few hundred meters. Giant pumice clasts are a product, and thus an indicator, of large, deep effusive eruptions. This eruption style partitions most of the mass into distal and global ocean basins, which has implications for how we interpret

past events and may ultimately lead to a re-evaluation of the volumes and magnitudes of submarine eruptions in the past.

AS is supported by NSF 1357216. MJ is supported by a National Defense Science and Engineering Graduation Fellowship. XRT was enabled by the Lawrence Berkeley National Lab Advanced Light source, beamline 8.3.2, and guidance from Dula Parkinson. Additional support was provided by the Marsden fund and the 2017 Student Mentoring and Research Teams (SMART) Program, Graduate Division, University of California, Berkeley. Fumihiko Ikegami created Figure 1d. Brian Monteleone provided assistance in SIMS analysis of melt inclusions at the Northeast National Ion Microprobe Facility. Melissa Rotella provided the raft clasts used in the floatation experiments. Thomas Giachetti provided assistance with He-pycnometry. We thank Tushar Mittal, Dan Fornari, Jocelyn McPhie, Ray Cas and an anonymous reviewer for comments, and the rest of the MESH team and Roger Revelle crew for making this science possible.

Author contributions. MM and WD modeled magma ascent. KF and CL performed the ingestion experiments and analysis. SM measured volatiles. CC measured composition. KF and BH did the floatation experiments. MJ measured porosity. KF and MM developed the clast ascent and ingestion model. All authors contributed to sample collection, interpretation and writing.

432

433 **Appendix**

434

435 **A. Why ingestion is not likely to be limited by permeability for large clasts**

436

437 As the interior of vapor-filled pumice cools, vapor condenses and draws in liquid water. Whether
438 heat loss or permeability limits this ingestion of liquid depends on the ability of a clast to lose
439 heat compared to the ability of liquid to flow into the clast – the slowest process will govern
440 liquid ingestion.

441

442 The condensation of vapor and heat loss from the clast is similar to the classic Stefan problem
443 except that advection of heat by liquid water drawn into the clast may dominate the heat
444 transport. An energy balance at the vapor-liquid interface balances the conductive transport
445 across that interface with the latent heat released

$$-\kappa \frac{dT}{dx} = \rho_s \phi L u \quad (\text{A. 1})$$

446 where u is the fluid velocity, L the latent heat, ρ_s is the density of steam, ϕ is porosity, T is
447 temperature, κ is the thermal conductivity of the liquid-saturated clast, and x is position. The
448 temperature distribution within the liquid-saturated part of the clast that determines the left-hand
449 side of equation (A.1) depends on u , and we use the solution for steady-state advective-diffusion
450 problem from Bredehoeft and Papadopoulos (1965)

$$\frac{T(x) - T_a}{T_s - T_a} = \frac{e^{\beta x/a} - 1}{e^{\beta} - 1} \quad (\text{A. 2})$$

451

where $\beta = ua/D$ is a dimensionless Peclet number (ratio of advection to diffusion of heat), where D is the thermal diffusivity of the liquid-saturated clast, a is the distance from the clast surface to the steam-liquid interface, and T_a and T_s are the temperatures of the ambient water and steam-liquid interface, respectively. The solution for the infiltration speed can be obtained by solving equations (A.1) and (A.2)

$$u = \frac{D}{a} \ln \left[1 + \frac{\kappa(T_s - T_a)}{\rho_s \phi L D} \right] \quad (\text{A. 3})$$

If permeability limits the infiltration speed of water, a lower bound on the velocity is given by Darcy's law assuming buoyancy controls infiltration

$$u > \frac{k \rho_w g}{\mu_w \phi} \quad (\text{A. 4})$$

where k is permeability, and μ_w is the viscosity of water. We use $>$ because we neglect the additional (and likely much larger) pressure gradients from gas contraction and capillary forces that would further increase u .

Whether heat loss controls infiltration (equation A.3) or permeable flow (equation A.4) depends on which is larger – the slowest velocity is rate-limiting. Permeability is not limiting if

$$k > \frac{\mu_w \phi D}{a \rho_w g} \ln \left[1 + \frac{\kappa(T_s - T_a)}{\rho_s \phi L D} \right] \quad (\text{A. 5})$$

Using $D = D_w \phi + D_r(1 - \phi) = 2.5 \times 10^{-7} \text{ m}^2/\text{s}$ for $\phi = 0.8$, where D_w and D_r are the diffusivities of water and glass, respectively (Bagdassarov et al., 1994), $\kappa = 2 \text{ Wm}^{-1}\text{K}^{-1}$, and conditions at the ocean surface ($T_s - T_a = 100^\circ\text{C}$, $\rho_s = 1 \text{ kg/m}^3$), we find that cooling is limiting provided $k > 1.5 \times 10^{-13} \text{ m}^2$ for a clast with $a = 1 \text{ m}$. Permeability of pumice is generally larger

than this value, typically $> 10^{-12} \text{ m}^2$ for vesicularities of 70-80% (e.g., Rust and Cashman, 2004; Mueller et al., 2005; Burgisser et al., 2017; Colombier et al., 2017; Gonnermann et al., 2018). Note that the value of k from equation (A.5) is an upper bound because we ignore additional pressure gradients driving water into the clast in equation (A.4) and densities and temperature difference at greater depths decrease the velocity predicted by equation (A.2). The model also neglects any interfacial instabilities that might enhance infiltration or change effective diffusivities (e.g., Randolph-Flagg et al., 2017).

B. Cooling, ingestion and ascent model

We model the density evolution and rise of hot and initially water vapor-saturated clasts. Clast density evolves due to internal gas decompression, contraction of vapor by cooling and condensation, and from liquid water infiltration. We assume that the clast vesicularity does not change due to volatile exsolution after clasts form. By coupling a model for clast density evolution to a model for clast rise speed (equation 3), we can estimate the time it takes clasts of varying sizes and vesicularities to reach the ocean surface from a depth of 900 m (Figure 6).

Consider a clast that is entirely filled with water vapor such that $f = 1$, where f is the fraction of pore space filled with water vapor. The clast has vesicularity, ϕ , initial temperature, T , diameter, D , and originates from a depth of 900 m. We assume an initial temperature of 850°C and calculate the initial density ρ_s , mass, m_s , and specific enthalpy, H , and total enthalpy, H_T , of internal the water vapor using a thermodynamic look-up table (IAPWS IF-97, XSteam;

Holmgren, 2006). We assume that the internal steam is fully coupled to the clast and cannot flow out unless the volume of steam exceeds the internal volume of the clast pore space. We calculate clast density as

$$\rho_c = \rho_r(1 - \phi) + \rho_s\phi f + \rho_w\phi(1 - f) \quad (\text{B.1}).$$

where the subscripts r and w stand for rock and liquid water. Clast density changes primarily as a function of the volume of internal water vapor, which in turn is affected by cooling and decompression. Clasts lose thermal energy through cooling according to

$$\frac{dH_T}{dt} = -qFS \quad (\text{B.2}),$$

where q is an average rate of heat loss that was measured experimentally to be approximately 7.5 W cm⁻² for initially air-filled pumice in water (Fauria, 2017), S is clast surface area, and F is a factor that describes the partitioning of latent heat within the water vapor and sensible heat within the glass. The ratio of sensible to latent heat in the clasts is characterized by the Stefan number

$$\text{St} = \frac{\Delta T c_p}{\phi L} \sim 1 \quad (\text{B.3}),$$

where ΔT , is the temperature difference between the initial clast temperature and ambient water, c_p is the heat capacity of the glass, and L is the latent heat of vaporization. We define

$$F = \frac{\phi L}{\Delta T c_p + \phi L} \quad (\text{B.4}).$$

The factor F accounts for sensible heat loss from the glass. That is, not all heat is drawn out of the internal water vapor, rather a proportion of cooling affects the glass. For an 850°C clast, we estimate $F \sim 0.5$. We find that precise value for F does not affect the calculated clast rise speeds, but is important for determining the minimum clast size that can reach the surface.

514

515 We calculate clast rise speeds as a function of clast density and size using equation (3). Clast rise
516 distance Z through the water volume is

517

$$Z = \int U dt. \quad (\text{B.5})$$

518

519 We relate depth h to pressure according to $P = \rho_w g h$. At each new depth we calculate the
520 density and volume, V_s , of the internal water vapor as a function of pressure and specific
521 enthalpy using a thermodynamic lookup table (XSteam; Holmgren, 2006). Internal water vapor
522 can expand as clasts rise through the water column, and contract due to cooling. The volume
523 fraction of pore space filled with water vapor is

$$f = \frac{V_s}{\phi V_c}. \quad (\text{B.6})$$

525

526 If the net effects of cooling, decompression, and gas expansion make the volume of internal
527 water vapor exceed the volume of the pore space such that $f > 1$, we let all excess water vapor
528 exit the pore space and set $f = 1$. We define the excess water vapor as $E_x = f - 1$. We write the
529 change in water vapor mass and total enthalpy due to vapor escape from the clast as

$$\Delta m_i = -E_x V_c \phi \rho_s, \quad (\text{B.7})$$

530

$$\Delta H_T = -\Delta m_i H. \quad (\text{B.8})$$

531

532 In contrast, cooling can make contraction and condensation exceed decompression effects such
533 that $f < 1$. If this is the case, we allow water liquid water to enter to pore space vacated by steam
534 due to condensation (e.g., Fauria, 2017), but does not decrease the clast's enthalpy. Equation

(B.1) demonstrates, however, how ingested water increases clast density and thereby affects rise speed, decompression rates, and clast fate.

We solve equations (3) and (B.1-8) using a first order finite difference scheme. The model ends when a clast either reaches the ocean surface or becomes neutrally buoyant due to vapor condensation and water ingestion. Figure 4 shows how clast size affects rise time to the surface and the minimum clast sizes required to reach the surface from a depth of 900 m. Below these minimum clast sizes, cooling results in vapor condensation and buoyancy reversal before a clast can reach the surface (Figure 4).

Many of the assumptions in equations (B.2-B.8) and approximations needed to develop this model could, in principle, be relaxed with a full 3D multiphase flow model that includes gas exsolution from the melt and mass, momentum and energy exchange with the surrounding water, and the presence of unconnected porosity (Figure 4). The model used here also neglects the buoyant ascent of warm water that would entrain clasts. A model that couples clast-scale processes and large scale dynamics may improve the accuracy of calculations of the fate of clasts and may reveal new and neglected processes.

If there is unconnected porosity, and all the connected porosity fills with liquid water, the unconnected porosity is able to keep clasts floating if

$$\phi_u = \frac{(\rho_r - \rho_w)}{(\rho_w - \rho_s)}(1 - \phi_t) \quad (\text{B. 9})$$

where the subscripts on density are as before and u and t indicate unconnected and total porosity, respectively.

559

560

Figure 1: a) Location of the Havre volcano (red circle) in the Kermadec arc. Inset shows the raft and plume on 19 July, 01:26 UTC. Inset scale bar is 20 km long. Plume and raft show the transport direction to the northwest. Example seafloor giant pumice clasts showing curvilinear surfaces (b) and typical deposit (c). d) Shaded relief map showing the vent location (triangle) at a depth of 900 m; arrow shows the dispersal axis of seafloor giant pumice (the same as the transport direction in a), and the light purple lines bound the region containing those clasts. Caldera is 4.5 by 5 km in size. Viewing direction is looking south.

568

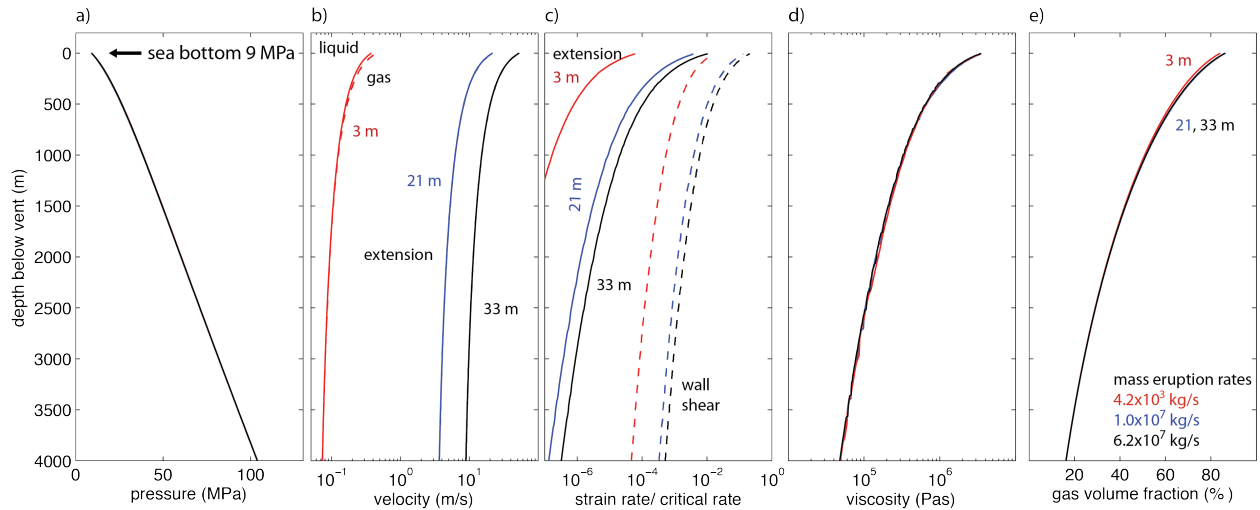

Figure 2: Magma ascent and gas escape, computed using the steady one-dimensional model of Degruyter et al. (2012) with melt properties for the Havre 2012 rhyolite eruption, showing how pressure (a), melt (solid curves) and gas (dashed curves) velocities (b), strain-rate relative to that needed to cause brittle fragmentation (c), magma viscosity (d), and vesicularity (e) varies with depth below the seafloor. Three conduit radii are assumed, 3, 21 and 33 m. Only the upper 4 km of the conduit are shown. Additional parameters: the percolation threshold for gas flow through the magma is zero, tortuosity factor is 3, bubble throat to radius ratio is 0.31, and the friction coefficient for gas flow through the magma is 10 (supplement S1 for details).

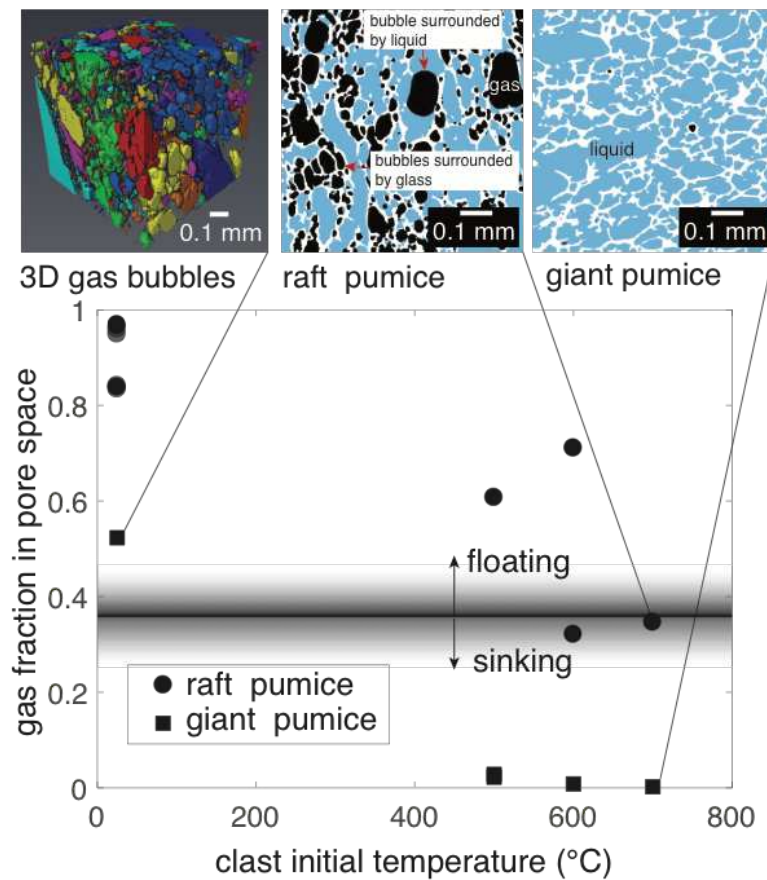

Figure 3: Initially hot pumice ingests more water than cold pumice, and giant pumice fragments (unknown locations within the larger clast) recovered from the seafloor ingest more water than pumice from the raft. A different pumice clast is used for each experiment and hence data point. The horizontal line shows the trapped gas fraction needed to keep a clast with a vesicularity of 80% buoyant. The two images on the upper right are 2D slices through their 3D images showing the distribution of glass (white), trapped gas (black), and liquid water (blue). Upper left shows the 3D shapes of trapped gas bubbles with a different color assigned to different gas bubbles.

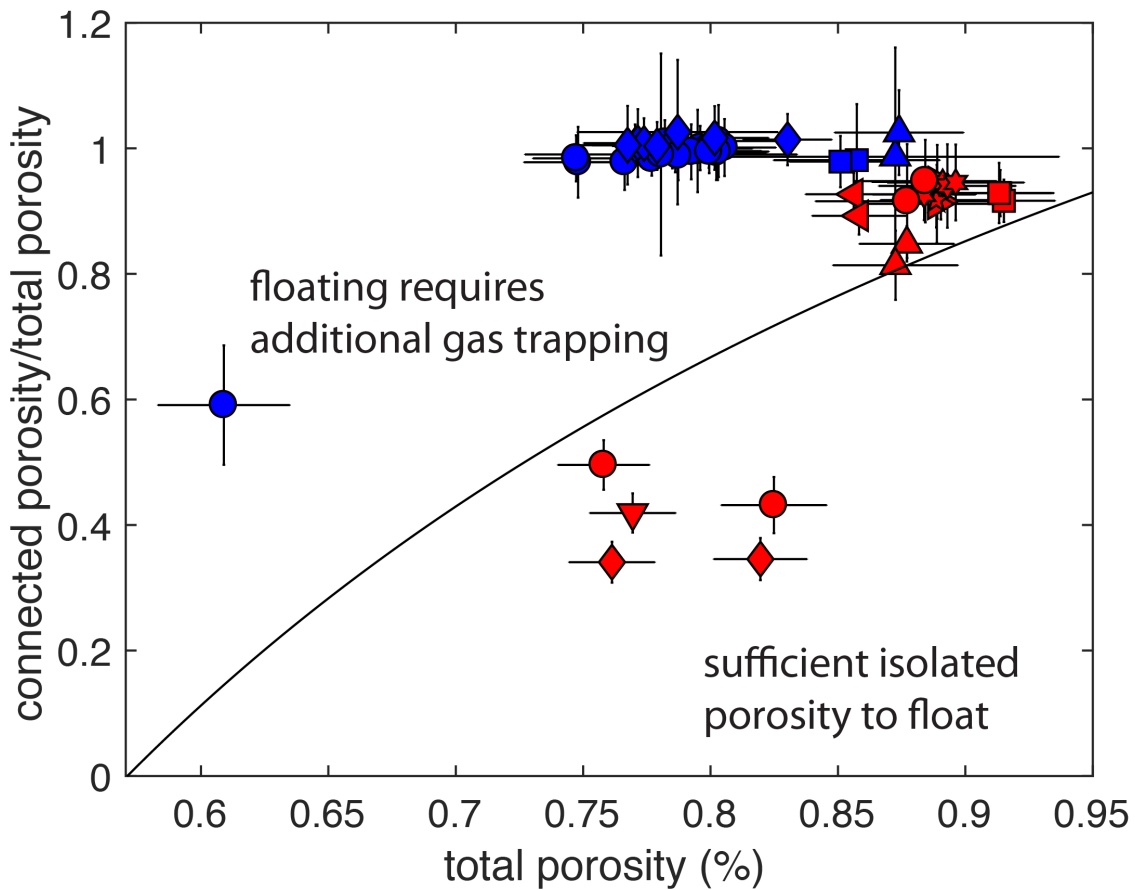

Figure 4: Connected fraction of total porosity vs. total porosity for sea floor giant pumice samples (red) and raft samples (blue). The measurements were conducted on multiple cores from three sea floor giant pumice samples and nine raft samples. Distinct samples are shown with different symbols. Excluding one sea floor measurement, which was collected from a breadcrusted exterior, the sea floor giant pumice samples all have $> 99\%$ connected porosity. All raft samples contain isolated vesicles. Shown with the curve is the amount of connected porosity needed, as a function of total porosity to allow clasts to sink if the connected pore space fills completely with water (equation B.9).

601

602

Figure 5: Clast volume versus floatation time (the time at which clasts sink). Data points above “still floating” show clasts that were still floating at the time of manuscript submission. Open data points represent clasts for which volume was calculated from weight and by assuming porosity; black data points represent clasts for which volume was measured using photogrammetry. From calculated porosity from mass and volume measurements we find that seafloor clasts have porosities of $85.6 \pm 3.2\%$. The grey bar represents a floatation time prediction from equation (2) and assuming $0.1 < \theta < 0.5$. The behavior of seafloor clasts matches the gas trapping prediction while that of raft clasts does not. Error bars are smaller than the data points.

Figure 6: Time required for clasts to reach the ocean surface from a depth of 900 m as a function of their size and vesicularity (assumed constant during ascent). Clasts with diameters smaller than those for which the curves begin (to the left of the curves) will ingest enough water to become negatively buoyant before reaching the surface. Rise speed evolves according to equation (2) and clast density is computed from the water ingestion model (appendix B).

622

623

624 **Figure 7:** Schematic illustration of the eruption of magma with Havre composition and water
 625 content, but at different depths: a) shallow enough that fragmentation occurs in the conduit, b)
 626 Havre vent depth, and c) deep or ascended slow enough that vesicularity is < 58%. In b), clast
 627 size in the raft decreases with transport owing to abrasion. Inset in each panel illustrates the
 628 manner in which clasts might form, either within the conduit (a), or quenching in water (b and c).
 629 Panel b) illustrates the settling of smaller clasts close to the vent, the rise of large, hot clasts to
 630 the sea surface, the trapping of hot pumice beneath the sea surface, and the settling of giant
 631 pumice out of the raft due to water ingestion. The relative temperature gradient of melt to glass
 632 in clasts given from orange to grey, respectively. White shapes are vesicles. Liquid water is blue.
 633 Not to scale.

S1 Conduit model parameters

Magma ascent is modeled assuming steady isothermal two-phase flow in a cylindrical conduit with constant radius. The flow is one-dimensional with all properties varying only with depth. The equations solved are identical to those in Degruyter et al. (2012) with fragmentation criterion given by (1) and a few modifications. We fit a model for melt viscosity with the same functional form as that in Hess and Dingwell (1996) with viscosity computed from Giordano et al. (2008) and measured composition (S3),

$$\log \mu = -3.62517 + 0.248398 \ln(100c) + \frac{9601 - 2368 \ln(100c)}{T - (195.7 + 96.4931 \ln(100c))}$$

where c is the water concentration in mass fraction and T is temperature.

The magma viscosity μ_m is given by

$$\mu_m = \mu(c, T) \theta(\chi) v(\phi)$$

where $\theta(\chi)$ accounts for the effects of crystals (5% assumed) on magma viscosity (Costa, 2005),

and

$$v(\phi) = (1 - \phi)^{5/3}$$

accounts for the effects of bubbles (Llewellyn and Manga, 2005).

Other parameters used in the model include a gas viscosity of 10^{-5} Pa s, a conduit length of 8100 m, magma temperature of 850 °C, melt density of 2400 kg m⁻³, initial water content of 5.8 weight %, initial pressure of 200 MPa, vent pressure of 9 MPa, bubble number density of 10^{14} m⁻³, tortuosity factor m of 3, friction factor f_0 of 10, a throat/bubble size ratio f_{tb} of 0.3125, and a percolation threshold of 0 (continuous percolation).

S2 Initial water content

Initial dissolved volatile contents c were measured using the CAMECA IMS 1280 secondary ion mass spectrometer at Woods Hole Oceanographic Institution, Massachusetts. H₂O, CO₂ and F contents were obtained from 16 plagioclase-hosted melt inclusions from a giant pumice block retrieved from the seafloor (Carey et al., in press). Melt inclusions analyzed had no visible fractures or pathways to the phenocryst edge and no vapor bubbles present.

Raw $^{16}\text{O}^1\text{H}/^{30}\text{Si}$ ratios from the SIMS were calibrated to H₂O wt % using calibration curves determined from a series of rhyolite standards and synthetic forsterite with known FTIR H₂O wt %. Likewise, CO₂ and F were determined using the raw $^{12}\text{C}/^{30}\text{Si}$ and $^{35}\text{F}/^{30}\text{Si}$ ratios from the samples and known CO₂ and F calibration curves from the standards. Measurements are summarized in Table S2.1.

H₂O and F contents were used in the initial melt viscosity calculation (supplement S1); F contents <0.1 wt % (1000 ppm) had a negligible effect on viscosity. Figure S2.1 shows that H₂O and CO₂ contents were also used to determine the initial model pressure of 200 MPa using the VolatileCalc solubility model (Newman and Lowenstern, 2002). H₂O-CO₂ isobars were determined for a rhyolitic melt at 850°C where all melt inclusions correspond to an average storage pressure of 200 MPa. The very low CO₂ contents (<150 ppm) justifies the use of only H₂O as the volatile phase within the conduit ascent model (S1).

836 **Table S2.1** Measured volatile contents in melt inclusions of seafloor pumice clasts

837

S3 Melt composition

XRF data given in Table S3.1 are the average for 5 giant pumiceous blocks sampled from the seafloor. Values match very well with those from Carey et al. (in press) and Rotella et al., (2015). Fe_2O_3 is corrected to FeO_t for use in the viscosity model (supplement S1).

We assume the initial melt composition is the same as the whole rock plus dissolved water.

Table S3.1 Whole rock composition.

SiO_2	TiO_2	Al_2O_3	FeO_t	MnO	MgO	CaO	Na_2O	K_2O	P_2O_5	Total	LOI
72.437	0.479	14.145	3.017	0.122	0.727	2.608	5.117	1.590	0.083	100.325	1.131

S4 X-ray computed microtomography

X-ray microtomography was performed on beamline 8.3.2 at the Advanced Light Source, Lawrence Berkeley National Lab. We used 30 kev monochromatic x-rays, a 5X lens to obtain a voxel size of 1.22 microns, and used 1024 images and the TomoPy gridrec algorithm (Gursoy et al., 2014) to create the 3D images.

To segment the 3D images into water, gas and glass, we used the Fiji trainable Weka segmentation algorithm (Hall et al., 2009) by manually outlining gas, liquid and glass and retraining the classifiers until the segmentation seemed accurate. The volume fraction of each phase was computed from the binary segmented images in Fiji. Aviso was used to make the images in Figure 4 and to identify distinct bubbles in the 3D rendering.

Supplement S5: Pumice floatation experiments

The seafloor clasts used here were fragments from decimeter pumiceous Havre seafloor samples HVR 020 and HVR 022 (Figure S5.1). We do not distinguish between HVR 020 and HVR 022 in our experiments because these two samples were mixed together when we retrieved them. The raft pumice was provided by Melissa Rotella from samples collected in New Zealand (Rotella et al., 2015), and the clasts we used were rounded by abrasion in the raft. These are different clasts than those used for the connected porosity measurements in Figure 4.

Figure S5.1: Havre seafloor clasts used in the pumice floatation experiments. HVR 020 and HVR 022 are both decimeter pumiceous clasts. The images show the clasts at the time of sample collection (Carey et al., in press).
